

Cornyebacterium

- ‘Cornye’ means club (club shaped swelling).
- It causes diphtheria.
Fact : Diphtheria bacilli described by klebs(1883).
Cultivated by loeffler (1884).
- Also known as Klebs-Loeffler bacillus.
- Morphology:
 - Slender rod-clubbing at one or both ends.
 - Pleomorphic
 - Metachromatic granules seen.
 - Arrangement of bacillus:
 - ✚ Pairs, palisade, V or L shape.
 - ✚ Chinese letter pattern
 - ✚ Cruciform arrangement
 - Staining done with Loeffler’s methylene blue show bluish purple metachromatic granules.
 - Special stains for demonstrating granules:
 - ✚ Albert’s stain
 - ✚ Neisse’s stain
 - ✚ Ponder’s stain
- Cultural characteristics:
 - Loeffler’s agar slant contains serum and egg that enhance the formation of metachromatic granules in C.diphtheria.
 - Also known as Bates-Ernst granules.
- Virulence factors:
 - For C.diphtheria to cause diphtheria, an exotoxin must be induced.
 - Heat labile polypeptide produced during lysogeny of β -phage that carries ‘tox’ gene.
 - Alkaline pH of 7.8 – 8.0, aerobic conditions and level of iron required for toxin production.
 - The toxin inhibits protein synthesis by ADP- ribosylating elongation factor- 2.
- Clinical significance:
 - Normally found in throats of healthy carriers.
 - Infects only man.

Diphtheria usually starts as a low infection of mucous membrane causing a membranous pharyngitis.

Local toxins causes degeneration of epithelial cells

Other symptoms are inflammatory edema, production of pseudomembrane composed of fibrin clots, leukocytes

- Pathogenesis:

- Most commonly seen in children o 2-10years.
- Incubation period is 3 to 4 days.
- Droplet spread
- Raucial diphtheria is the common type.
- Toxin has both local and systemic effects.
- Systemic effects:
 - ✓ Affects the
 - ✚ heart- heart failure
 - ✚ Peripheral nerves- paralysis
 - ✚ Adrenal glands- hypofunction
 - ✓ Cutaneous diphtheria – necrotic lesions with occasional formation of a local pseudomembrane occur.

- Diphtheria clinical classification:

- Epidemiology:

- Formerly important paediatric disease.

- Rare in 1st year of life, peak between 2-5years, fall slowly between 5-10 years and rapidly between 10-15 years.
- Laboratory diagnosis:
 - Isolation of the organism.
 - Demonstration of its toxicity.
- Isolation:
 1. Collection of specimen – 2 swabs
 - a) Smear examination
 - b) Culture
 2. A source of light and tongue depressor are necessary for visualisation of post-pharyngeal wall.
 3. Swabs – rubbed over the pseudomembrane.
- Microscopy:
 - Blots
- Culture:
 - Loeffler's serum
 - Tellurite blood agar
 - Blood agar
- Biochemical reaction:
 - Hiss's serum
- Subcutaneous test:
 - 0.8 ml of overnight broth culture ingested to 2 guinea pigs.
 - One of them is protected with 500 units of diphtheria autotoxin 18-24 hr prior.(control)
 - If the strain is virulent, the unprotected animal dies within 2-3 days with haemorrhage in adrenal gland (**pathognomonic feature**)
- Intracutaneous test:
 - Two guinea pigs injected intracutaneously with 0.1ml emulsion,one animal is protected with 500 units of antitoxin given on the previous day.(control)
 - Test animals- 50 units antitoxin given intraperitoneally 4 hrs after intracutaneous injection in order to prevent death.
 - If the strain is toxigenic – inflammatory necrosis at the site. If infection seen in test animals.
- Invitro test:
 - Elek's gel precipitation test.

- Treatment:
 - Penicillin – sensitive
 - Erythromycin – more active in treatment of carriers.
 - Antidiphtheric serum should be given immediately – 20,000 units IM.
 - Severely ill cases – 50,000 to 1,00,000 units given.
